Attacks and Remedies in Collaborative Recommendation

The goal of this project is to explore the vulnerabilities of recommendation and personalization systems in the face of malicious attacks, explore techniques for enhancing their robustness, and examine methods by which attacks can be recognized and possibly defeated.

Collaborative Recommendation: Highly Vulnerable

Collaborative filtering (CF) recommendation is commonly used in e-commerce. Users' preferences are represented by profiles that consist of ratings for products. Such systems identify peer users with similar tastes and extrapolates their ratings as likely to be similar to the target user. The standard formulation of CF is highly vulnerable to attack. An attacker can insert a large number of fake profiles to bias the system's recommendations for or against certain products.

Securing Collaborative Recommendation

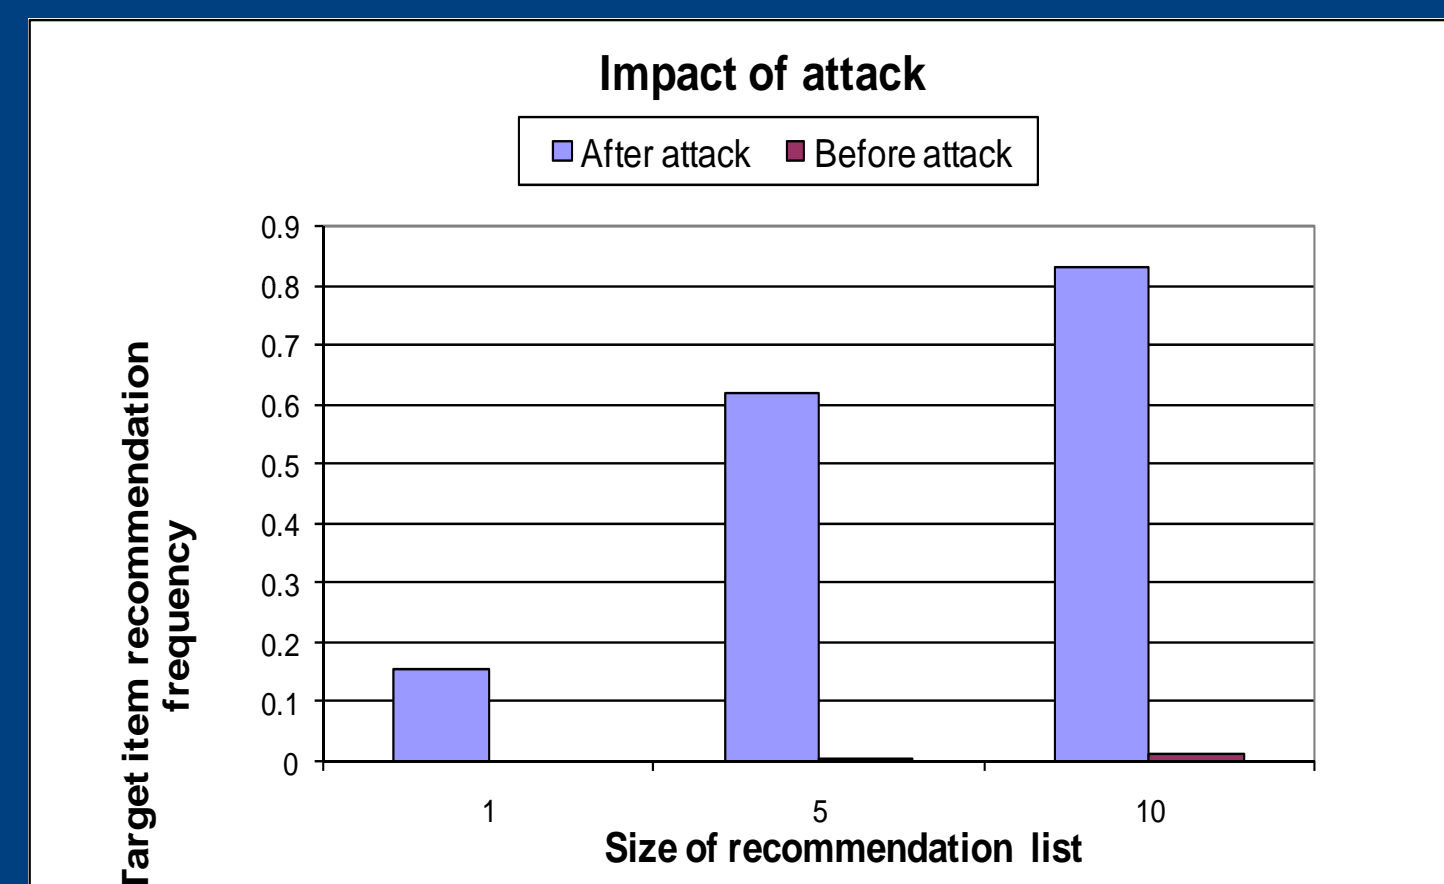

Our research has focused on the development of more robust algorithms as well as methods for attack detection.

Algorithms: We have explored the spectrum of possible attacks against recommendation systems, and developed models characterizing these attacks and their impacts. We have examined a range of recommendation algorithms including user-based, item-based and model-based collaborative recommenders, and developed a more robust hybrid algorithm, combining collaborative with content-based and knowledge-based techniques.

Detection: Our approach to attack detection is based on classification learning:

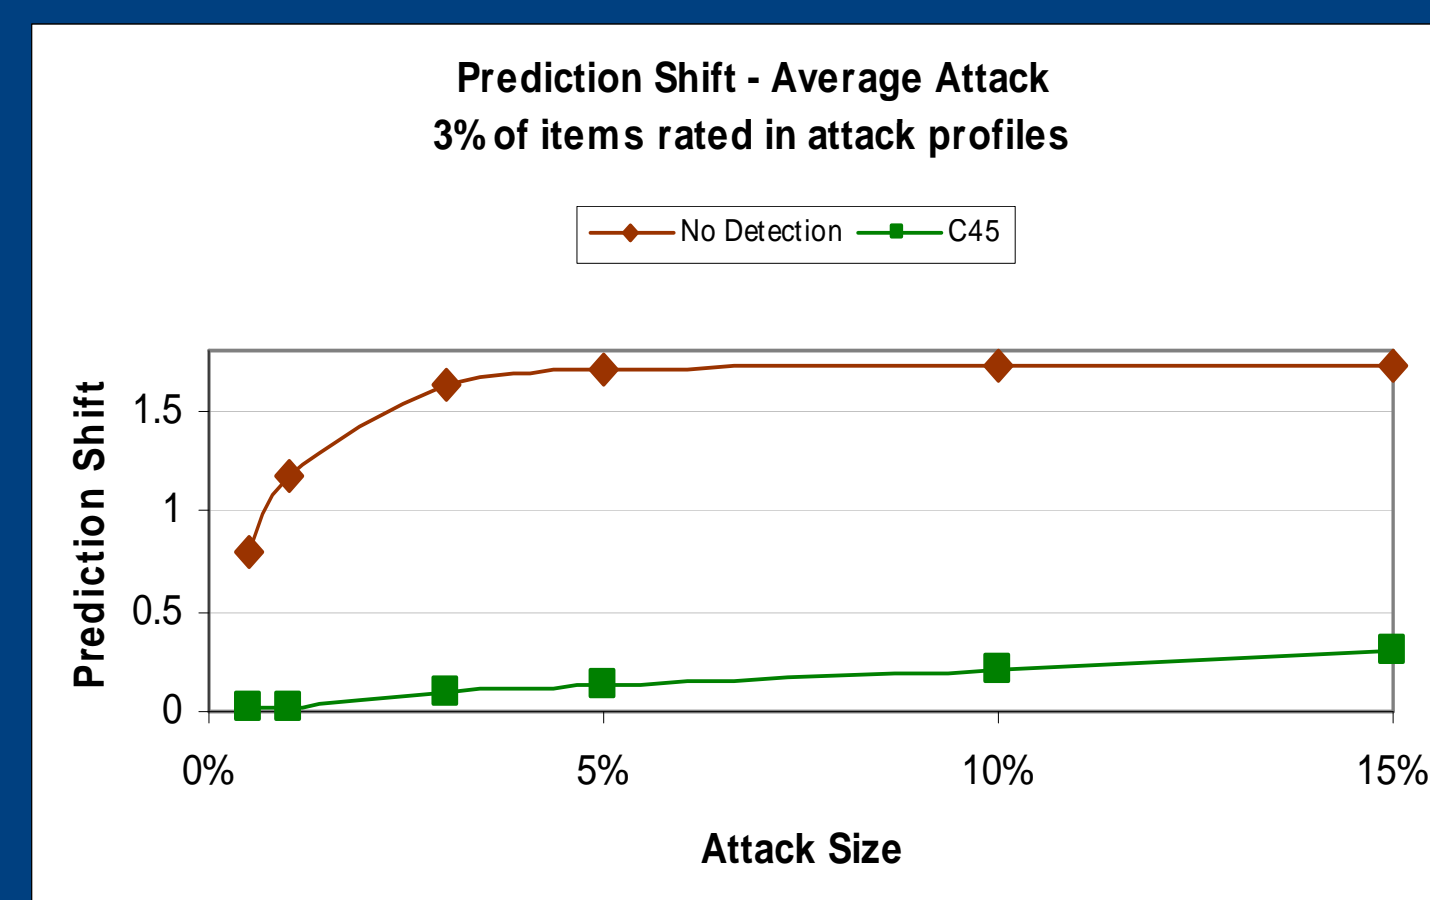

- Create attributes that capture characteristics of suspicious profiles
- Use attributes to build classification models
- Apply model to user profiles to identify and discount potential attacks

Example: **Bandwagon attack**. Profiles use popular items to *push* a target item.

After the attack, item appears in 80% of top 10 recommendation lists.

Example of attack detection results, using C4.5 Decision Tree model.

Prediction shift (rating scale of 1-5) due to attack, with and without detection.

Summary of Findings

Theoretical Framework for Attack Model: Has enabled the systematic study of profile injection attacks and their properties.

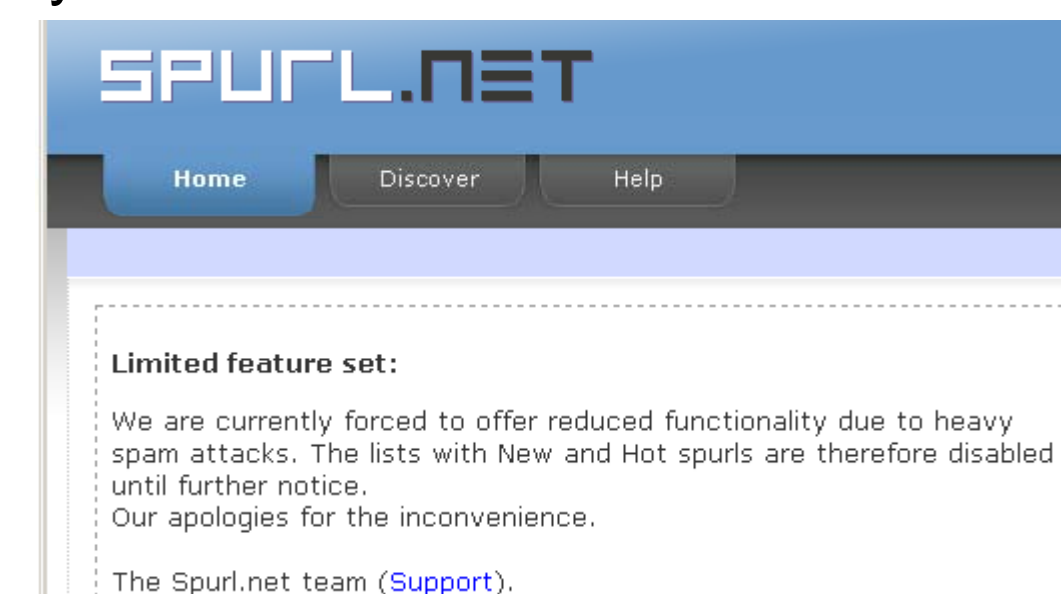

New Algorithms: Significant advantage for hybrid recommendation (knowledge-based & collaborative). Also, certain model-based algorithms are more robust with minimal loss in prediction accuracy.

Attack Detection: Profile classification approach based on attack model specific attributes has led to highly effective approach for detecting most attack models.

Anomaly Detection: Classify items (as being under attack). Not dependent on known attack models, and can determine which type of items are most vulnerable to which types of attacks.

Real world impact

Examples of "shilling" are well-known in the industry. One e-commerce site found that a manufacturer was using off-shore sub-contractors to enter favorable reviews of its products. Amazon.com has found authors pseudonymously reviewing their own books. Secure recommendation algorithms would increase user trust and allow site operators to realize greater benefits from recommender systems.

In 2008, bookmark sharing site spurl.net had to eliminate services in response to profile injection attacks.

Extensions

Social Networking / Tagging Systems: Tagging systems allow users to associate their own labels (tags) with resources, such as images or URLs. The bookmark sharing site Del.icio.us and the photo site flickr are examples. In Del.icio.us, attackers can promote their sites by creating multiple profiles in which their URLs are closely related to popular tags; such attacks are already a well-known problem in these sites. We are extending our approach to encompass these systems: to model attacks and their outcomes and to propose remedies.
